Abstract—Goldbach conjecture is one of the most famous open mathematical problems. It states that every even number, bigger than two, can be presented as a sum of 2 prime numbers. In this work we present a deep learning based model that predicts the number of Goldbach partitions for a given even number. Surprisingly, our model outperforms all state-of-the-art analytically derived estimations for the number of couples, while not requiring prime factorization of the given number. We believe that building a model that can accurately predict the number of couples brings us one step closer to solving one of the world most famous open problems. To the best of our knowledge, this is the first attempt to consider machine learning based data-driven methods to approximate open mathematical problems in the field of number theory, and hope that this work will encourage such attempts.

I. INTRODUCTION

On June 1742, the mathematician Christian Goldbach wrote a letter to his friend, Leonard Euler, describing his conjecture that states that every even integer is a sum of two prime numbers [Goldbach1742]. Since then expert mathematicians, students and many others have tried to prove this conjecture or disprove it. Even though more than two hundred and fifty years have passed, the conjecture remains open. The conjecture can be checked directly for limited sets of numbers. To this date, Goldbach’s conjecture has been verified up-to $10^{11}$ primes [Oliveira e Silva et al. 2014]. During the past centuries, despite no actual proof being found, there has been some important and significant progress related to this conjecture. In this paper, we focus on approximation of the Goldbach’s function, denoted by $G(n)$. This function returns the number of Goldbach partitions that a given number has [Fliegel and Robertson1989]. Rephrasing Goldbach’s conjecture in terms of Goldbach’s function would state that the value of Goldbach’s function (for all even numbers greater than 4) is greater than or equal to 1. For example, $G(8) = 6$, because 8 = 2 + 6 = 3 + 5. See Figure 2 for an illustration of Goldbach’s function on the first 100 even numbers. The plot of the Goldbach function has a form of a comet and is consequently called “Goldbach’s comet” [Fliegel and Robertson1989] (See Figure 1 for Goldbach’s function values for all even numbers between 4 and $4 \times 10^6$).

Several works have suggested different approximations for Goldbach’s function which they have derived analytically. Unfortunately, some of these approximations are very far from the actual values taken by Goldbach’s function, while others require prime factorization (prime decomposition) which is believed to be an intractable operation on large numbers.

In this paper we suggest a different approach to approximating Goldbach’s function, we propose using a deep learning approach.

It may seem that deep learning is not a suitable approach for this type of problems, as the input to the approximation function is only a single number, and deep learning has shown success in situations in which the input is composed of a large vector or a matrix. We therefore propose a simple, yet powerful concept of translating the number into different bases. Surprisingly our approach outperforms current state-of-the-art approximations of Goldbach’s function, resulting in an error rate of only 3.0%. Furthermore, our method does not require prime factorization of the number, which is intractable for large numbers. We believe that our model may shed light on the behavior of Goldbach’s function and may bring us one step closer to proving or disproving Goldbach’s conjecture. Furthermore, introducing deep learning to the field, may assist in proving or disproving other similar open mathematical problems.

II. BACKGROUND

Prime and natural numbers have always aroused mathematicians’ interest. In 1900 Hillbert made his famous speech at the 2nd International Congress of Mathematics held in Paris, saying there are 23 unsolved problems for mathematicians of the 20th century [Wang2002]. One of those math problems was Goldbach’s conjecture.

A. Approximations for Goldbach’s Function

Goldbach’s Conjecture is divided into two conjectures:

1) The ‘weak’ Goldbach’s conjecture states that ‘Every odd number greater than 5 can be expressed as a sum of three primes’. For example, 11 is the sum of 3, 3 and 5. 21 is the sum of 2, 2 and 17. The weak conjecture was finally proved in 2013 [Helfgott2013].
2) The ‘strong’ Goldbach’s conjectures which states that ‘Every even integer greater than 2 is a sum of two primes’. The number 6 for example, can be presented with only one pair of prime numbers, \(3 + 3\). However, when examining even numbers greater than 12, there are apparently, at least two pairs of prime numbers that sum to each even number, for example, \(14 = 7 + 7\) and \(14 = 3 + 11\). One might assume that the greater the even number, the more different pairs it has, yet by observing different even numbers this assumption turns out to not always hold. For example, while 34 and 36 have 4 Goldbach partitions each, 38 has only 2 Goldbach partitions as is shown in Figure 2. This conjecture remains open until this date.

In this paper we focus on Goldbach’s function which provides the number of Goldbach’s partitions an even number has. More formally, Let \(n \in \mathbb{N}\), the Goldbach’s function is given by:

\[
G(n) = \sum_{(p,q) \in \mathbb{P} \times \mathbb{P} \land p \leq q} 1\{p + q = n\} \tag{1}
\]

where, \(\mathbb{P}\) is the set of all prime numbers, and \(1\) is the indicator function that returns 1 if the expression is true and 0 otherwise.

Over the years there have been several attempts to find an analytic approximation to Goldbach’s function. Hardy and Littlewood [Hardy and Littlewood1922] proposed the following approximation:

\[
G_1(n) = 2 \cdot C_2 \frac{n}{(\ln(n))^2} \prod_{p|n} \frac{p - 1}{p - 2} \tag{2}
\]

where \(C_2\) is their twin prime constant:

\[
C_2 = \prod_{p \geq 3} \left(1 - \frac{1}{(p - 1)^2}\right) \approx 0.6601618158 \tag{3}
\]

\(n\) denotes an even number, and \(p\) denotes all the prime factors of \(n\). While this function was originally proposed as an upper-bound, it is widely used as an approximation. Baker, suggested multiplying \(G_1(n)\) by \(\frac{3}{2}\) to yield a better approximation [Baker2007] (we will refer to Baker’s approximation as \(G_2(n)\)).

Note that this approximation requires factorizing \(n\), which is assumed to be a hard problem. Currently, best known prime factorization algorithm (GNFS) [Buhler et al.1993] runs in time complexity of:

\[
O\left(\exp\left(\left(\sqrt[3]{\frac{64}{9}} + o(1)\right)\sqrt[3]{\log(n)}\sqrt[3]{(\log\log(n))^2}\right)\right)\]

where \(n\) is the number being factored. Note that the input size is considered \(\log(n)\), since the number of digits required to represent \(n\) is \(\log(n)\).

To overcome this prime factorization requirement, the following approximation was proposed [Provatidis et al.2013]:

\[
G_3(n) = \frac{n}{(\ln(n))^2} \tag{4}
\]

This approximation is derived from Gauss’ approximation provided in 1793 for the probability of a number being prime. According to Gauss, this probability is given by:

\[
f(m) = \frac{m}{\ln(m)}\]

Therefore, for an even number \(n\) the following may be used as an approximation for its number of Goldbach partitions:

\[
\sum_{m=3}^{n/2} \frac{m}{\ln(m)} \cdot \frac{n-m}{\ln(n-m)} \approx \frac{n}{2\ln(n)^2} \tag{5}
\]

Note that \(G_3\) is monotone, and thus cannot capture the phenomenon that larger numbers may sometimes have less Goldbach partitions than smaller numbers. The following approximation, which is also monotone, was proposed by Markakis et al. in [Markakis et al.2012]:

\[
G_4(n) = \frac{n}{(\ln(n/2))^2} \tag{5}
\]
B. Related Work

In addition to attempts for finding an approximation to Goldbach’s function, there have been several attempts to finding upper and lower-bound to it, that is, a function that limits the number of Goldbach partitions from above or below. The \( G_1(n) \) function proposed by Hardy and Littlewood [Hardy and Littlewood1922] was originally suggested as an upper bound. One proposed lower-bound function provided by Provatidis et al. [Provatidis et al.2013] is:

\[
2/3 \times G_1(n)
\]  

(6)

This lower-bound was derived analytically, and it is shown that as \( n \) grows, the probability of it having less Goldbach partitions than the lower bound approaches 0. However, proving this lower-bound as a strict lower-bound, would imply the proof of Goldbach’s conjecture, since this lower-bound is at least 1 for every even number.

Montgomery and Vaughan define another function related to Goldbach’s conjecture, capturing non-Goldbach numbers, that is, numbers that cannot be written as a sum of two prime numbers [Montgomery and Vaughan1975]. Montgomery and Vaughan’s function, \( E(n) \), denotes all even numbers smaller than \( n \) that are not a Goldbach number. Montgomery and Vaughan prove that there exists an absolute constant \( \delta > 0 \) such that

\[
E(N) \ll N^{1-\delta}.
\]  

(7)

There are several fields lying in the intersect of artificial intelligence and mathematical problems. Automated theorem proving [Bibel2013] is a field in which machines use various artificial intelligence based methods, such as heuristic search, in an attempt to find a proof for a given conjecture. In 1956, Newell and Simon developed the “Logic Theorist” [Newell and Simon1956]. The Logic Theorist was based on heuristic search and successfully proved 38 of the 52 theorems that appear in the second Chapter of Principia Mathematica [Whitehead and Russell1912].

The ‘Automated Mathematician’ (AM for short) was created by Douglas Lenat in Lisp. [Lenat1977]. AM used heuristic search to find interesting properties in mathematics. AM defined 250 various heuristics and tried to infer different mathematical properties by applying these heuristics. AM discovered the concept of natural numbers, prime numbers, it conjectured (without proof) the unique prime factorization theory and defined the concept of Goldbach partitions. Unfortunately, AM was not able to discover any “new to mankind” mathematics, and it turned out to be very hard for it to discover new heuristics. One of the statements Lenat’s AM produced was the Goldbach conjecture [Larson2005]. AM was more about finding interesting problems than solving them. An improved system named EURISKO was later developed by Lenat, with an attempt to learn these heuristics by its own [Lenat1983], [Lenat and Brown1984].

Colton et al. [Colton et al.2000] developed an artificial intelligent system for identifying mathematical concepts, such as, types of graphs, types of groups and types of numbers. For example, their method can identify that a sequence such as 1, 4, 9, 16 etc. is a sequence of squared numbers. They state that the state-of-the-art at their time for identifying these concepts was just a data-base.

III. DEEP LEARNING BASED GOLDBACH’S FUNCTION APPROXIMATION

In this section we present a deep learning based model to approximate Goldbach’s function values.

A. Data Composition

In order to train and evaluate the different methods, we composed a data-set consisting of the number of Goldbach partitions that all even numbers from 4 to \( 4 \times 10^6 \) have. To that end, we first computed all prime numbers at that range, and stored them as a list and as a hashmap. For each even number, \( n \), we iterated on all prime numbers (using the list of all primes) that are smaller than or equal to \( n/2 \). For each of these prime numbers, \( p \) we test (using the hashmap) whether \( n-p \) is a prime number itself. If so, we increment \( n \)’s counter by one.
We shuffled the data and split it into a train set, (80% of the data; $16 \times 10^5$ numbers), a validation-set, (10% of the data; $2 \times 10^5$ numbers), and the remaining 10% was reserved for the test-set ($2 \times 10^5$ numbers).

### B. Model Features

From each number we extracted 42 features. We converted every number to its binary representation, ternary representation (base 3), quinary representation (base 5) and septenary representation (base 7). The time complexity of computing these base representations for a number $n$ is $O(\log(n))$. In practice we computed these representations when composing the data, so we simply incriminated the representation of the previous number by 2 for all bases. We truncated these representations and used the 10 least significant digits for each representation. The intuition behind using these different representations lies in the fact that these transformations are computationally cheap to extract and that they might allow the model to retrieve underlying information on the number. The first 4 prime numbers $(2, 3, 5, 7)$ were selected as the bases. In addition to the representations in the different bases, we added the number itself (normalized), and the logarithm of that number.

### C. Model Architecture

We used a fully connected neural network as our model. We set the number of neurons to 200 on each hidden layer. We used Adam optimizer [Kingma and Ba2014], with a learning rate of 0.001. We used a mini-batch size of 1024 and trained the model for approximately 200 epochs on the data. We used early stopping [Prechelt1998], that is, we evaluated the validation set every epoch and saved the variables which obtained the lowest validation error. We varied the number of hidden layers, starting at a simple linear regression model (with no hidden layers), a model with 3 hidden layers, 5 hidden layers, and 7 hidden layers. Each of these models was trained on the training data and their performance was evaluated on the validation set. See Table I for a summary of the validation results. As can be seen in the table, the model with 5 hidden layers performed best on the validation set, and was therefore chosen as the model for our further analysis. For a given number $n$, the time complexity of generating the features and evaluating our model is $O(\log(n))$, which is the best time complexity one could expect from an algorithm that reads the entire input (which requires $O(\log(n))$ digits to represent).

**Table I:** Train and validation mean squared error (MSE) according to the number of hidden layers. We select the model with the lowest validation error (5-hidden layers).

### D. Results

Table II presents the performance of our model in comparison to the formulas that appear in the literature, in terms of mean squared error (MSE), root mean squared error (RMSE) and the error rate in comparison to the number of actual pairs (that is, the RMSE divided by the mean of the number of Goldbach partitions each number in the test-set has). In addition to the analytically derived estimations, we also considered K-Nearest Neighbors (KNN) as another baseline (with the K set to 105 neighbors, as that value performed best). As can be seen in the table, our model outperformed all previous approximation attempts, achieving a new state-of-the-art approximation model. Furthermore, our model does not require factorizing the given number. Figure 3 compares the approximation of the different methods on 20 randomly sampled numbers from the test-set. As illustrated in the figure, our approach achieves the best fit to the actual points. While $G_3$ and $G_4$ follow the average value of Goldbach’s function, they do not follow the ups and downs of it. $G_1$ does follow the ups and downs of Goldbach’s function but keeps a gap all along the plot. While this gap is corrected nicely by $G_2$, $G_2$ (as well as $G_1$) requires prime factorization to be computed.

Using our trained model, we tried to articulate what a number violating Goldbach’s conjecture may look like. We used a hill climbing search method on the base representations of the input features to the model. We set the number itself to $10^6$ and its log value accordingly. Iteratively, we traversed each of the digits of each of the base representations, searching for the digit value that minimizes our model’s prediction. We repeated this process until no digit was changed. Table III presents the base representations of a hypothetical number found by the search method. According to our model, this number violates Goldbach’s conjecture, with a prediction of -192,886 Goldbach partitions (note the negative value). This number is a factor of 14, has a remainder of 2 when divided by 3 and a remainder of 4 when divided by 5. We performed a search on numbers satisfying base 7 representation, that is, numbers of the form $m \times 7^{10} + \cdots + 6 \times 7 + 1$, $m \in \mathbb{N}$, and tested whether these numbers satisfy also the other bases representations. While such numbers are likely to exist, our attempts for finding such a number have failed, and we conclude that no such number exists that is smaller than $10^{19}$. Furthermore, even if we found such a number, once we plug-in the number to the model, it might predict a value larger than 0, and even if our model predicts a value less than 0, it is very well likely that our model does not perform that well when considering numbers so much larger than those it was trained on.

### E. Feature Analysis

In this section we analyze the contribution each of the features has on the performance of the model. Table IV presents the performance of the model (in mean squared error) when trained without each of the following sets of features: base 2, 3, 4, 5 and 7 representation, without the number itself and without its log. As can be seen in the table, the base-3 features seem to have the greatest impact on the model,
TABLE II: error of the deep learning based method in comparison to the state-of-the-art approximations. Asterisk (*) denotes models that require prime factorization of the given number.

Fig. 3: Prediction of the different methods on 20 randomly picked numbers from the test-set. The asterisk (*) denotes models that require prime factorization of the given number.

TABLE III: Base representations of a hypothetical even number violating Goldbach’s conjecture, with our model predicting a negative value of Goldbach’s partitions for it.

TABLE IV: Mean squared error (MSE) of model trained on a subset of the features.

IV. DISCUSSION

As stated in the introduction, Goldbach’s conjecture has been verified up-to $4 \times 10^{18}$. This verification was performed by using exhaustive search. Our approximation model may allow a selective search method in which Goldbach’s conjecture can be verified only for suspicious numbers according to our model, that is, only numbers that our model predicts will have a very low number of pairs. This approach can also be used to find numbers that violate the lower-bound proposed by [Provatidis et al.2013]. However, such selective search may require retraining our model on data closer to the target distribution (i.e., larger numbers), and adding additional digits to the base representations.

The success of our method can be attributed, for the most part, to the base representations added as features. In our work we used based representations for the first 4 prime numbers (2, 3, 5, 7), though it is likely that adding few additional base representations with the following prime numbers (e.g. 11, 13, 17), would increase the model’s accuracy. However, it is...
impractical to add more than a few additional representations (adding all prime representations up to the given number would require prime factorization, which is the exact problem our method tries to avoid).

In this paper we do not attempt to use DNN for actually proving a theorem (which is a completely different field), but believe that DNN can be used to help solving open mathematical problems in different ways, the first is by finding counterexamples (e.g. using selective search, as mentioned in the paper), the second is by analyzing the features that the DNN considers when computing its values. In our example we show that using different base representations (which can be computed cheaply) is very useful for computing Goldbach's Conjecture, (as opposed to the expensive prime factorization computation which was previously known). Future advancements in explainable neural networks, might help shedding additional light on this problem when applied to our results.

One of the main requirements for machine learning based methods to perform well is that the train and test data both come from the same distribution. Therefore, if the test data comes from a different distribution (e.g. higher numbers), it is likely that our model will not perform that well. Nevertheless, while testing our model with higher numbers (between 4,000,000 and 5,000,000), our model (trained on numbers between 4 and 4,000,000) resulted in a RMSE of 655.8, which still significantly outperforms models $G_3$ and $G_4$ which both require prime factorization. Note that our additional baseline of KNN is impractical when the distributions of the train and test data do not match.

While deep learning has shown great success in many different fields [Lv et al.2015], [Cruz-Roa et al.2013], [Alipanahi et al.2015], we believe that the success shown in this paper related to an open mathematical problem in number theory, is a big step and should not be disregarded as being merely another deep learning application. Our work may lead to a new paradigm of using deep learning (or machine learning in general) to solve mathematical problems such as prime factorization, friendly numbers, finding prime twins and many similar problems, which may currently seem out of the scope of deep learning methods.

V. CONCLUSIONS

Goldbach’s conjecture and Goldbach’s function have remained open mathematical questions for over two and a half centuries. There have been several analytic attempts to approximate Goldbach’s function, but unfortunately, these approximations either do not work well in practice or require prime factorization (prime decomposition) which is a hard problem. In this paper we present the first deep-learning based approach to approximating Goldbach’s function. We show that our approach outperforms current state-of-the-art approximations while not requiring prime factorization. We believe that our results can bring us one step closer to solving one of the worlds most significant open mathematical question.
